1. Introduction

2. Sea level projections (PG)

2.1. Global sea level

Most climate models do not explicitly provide sea level as an output of the calculations. Rather, the IPCC AR5 report [Stocker *et al.*, 2013, ch. 13] combines the heat expansion of the ocean with temperature forced models for glacial melt, Greenland ice melt, and Antarctic ice melt and with land rise due to rebound from the last ice age. Judging from the supplementary material to Stocker *et al.* [2013, ch. 13], the uncertainty assessment is only based on the spread of the ensemble of temperature projections, not on the additional uncertainty in the ice models used.

We will instead use the empirical approach of Rahmstorf and collaborators [Rahmstorf, 2007; Rahmstorf *et al.*, 2011], employing the statistical modeling of Bolin *et al.* [2014] to relate global annual mean temperature anomalies [Hansen *et al.*, 2001] to global mean sea level anomalies [Church and White, 2011].

We then apply the estimated historical relationship to projected temperatures from the CMIP5 experiment [Taylor *et al.*, 2012] to obtain projected global annual mean sea level, taking into account the uncertainty in the statistical model as well as the spread of the temperature projection ensemble (see subsection 2.3). For the i 'th temperature projection T_t^i we estimate the corresponding global mean sea level as

$$H_t^{gl,i} = \int_{t_0}^t \hat{a}(T_u^i - \hat{T}_0) du + \varsigma_t$$

where \hat{a} and \hat{T}_0 are regression parameters of observed global sea level on observed global temperature and ς_t the integrated time series regression error.

2.2. Local sea level

In order to get from global sea level projections to local ones, it is important to note that sea level rise not is uniform over the globe. Glacial and land ice melting affect the local sea level differently depending on where the melted ice is located. Another major effect in Fennoscandia is the land rise due to isostatic rebound from the glaciers of the last ice age. Again, we will use historical data to relate global sea level to isostatically corrected local sea level using a time series regression model. The local sea level projections are then obtained by first relating projected temperature to global sea level, and then relating the global sea level to the local one. Each climate model temperature projection yields a different local sea level projection. The local sea level projection based on the i 'th climate model for years beyond 2000 is estimated as

$$H_t^{loc,i} + \gamma(t - 2000) = \hat{b}H_t^{gl,i} + \varepsilon_t$$

where γ is the annual land rise rate, t and \hat{b} is the regression coefficient relating global to local sea level.

2.3. Uncertainty assessment

Following the approach of *Guttorp et al.* [2014] we assess the uncertainty in the local sea level projections taking into account the variability between the climate projections used, the uncertainties in the regressions of global mean temperature on global mean sea level and of global on local sea level. We express the sea level projection uncertainty in

terms of a confidence band that is simultaneously of the intended level for all projection years. This allows us, for example, to get a confidence band for the years when a given sea level rise is obtained.

2.4. Limitations of the sea level projections

The main assumption is using historical relationships in statistical projections of the type used in this paper is that there is no major change in how temperature relates to sea level, globally and locally. Among the factors that may invalidate this approach are changes in water storage on land (in essence removing water from the oceans), excessive siphoning of groundwater (resulting in land subsidence), changes in the rates of glacial and land ice melt, and changes in Earth's gravitational field due to transfer of mass from land ice to ocean water. For example, the rate of ice melt on Greenland may suddenly increase substantially due to intense warming of both air and sea water. Our current climate models are not able to resolve the ice processes sufficiently to include such so called tipping points into the projections. Also, the IPCC scenarios [*van Vuuren et al.*, 2011] do not include changes in water usage.

3. Decision tools (KdB, MD, TT)

3.1. Timing of adaptation measures

We consider adaptation decision making related to the timing of proactive adaptation measures. That is, the goal is to adapt to sea level rise before major damages occur. In a cost-benefit framework, an investment should be delayed as long as the benefits of delay (avoided investment costs) are greater than the associated costs (higher climate change damages) [*Fankhauser et al.*, 1999].

We assume that damages related to sea level rise coincide with damages due to storm surges and that the accumulated annual damages are independent between years. More specifically, we model the distribution of annual damage, F_d , by the three parameter Burr distribution [Burr, 1942] with density

$$f_d(x) = \frac{\alpha\gamma(x/\theta)^\gamma}{x[1 + (x/\theta)^\gamma]^{\alpha+1}} \quad (1)$$

for $x > 0$, where α and γ are shape parameters with $\alpha, \gamma > 0$, and $\theta > 0$ is a scale parameter. The Burr distribution has a heavy upper tail and is commonly used to model damage loss, see e.g. Klugman et al. [2012].

Under a constant sea level, we can obtain a sample trajectory $\{d_{t_1}, d_{t_2}, \dots, d_{t_{85}}\}$ of future annual damages for $t_1 = 2016, \dots, t_{85} = 2100$ by drawing 85 i.i.d. values from the estimated damage distribution for $t_0 = 2015$, \hat{F}_{d,t_0} . By repeating this process J times, we obtain an empirical damage distribution for each future year t_i given by

$$\hat{F}_{d,t_i}(x) = \frac{1}{J} \sum_{j=1}^J \mathbb{1}\{d_{t_i}^{(j)} \leq x\}$$

for $i = 1, \dots, 85$. Similarly, we obtain an empirical distribution of the total damage over the period 2016 – 2100 by considering $d_{\text{total}}^{(j)} = \sum_{i=1}^{85} d_{t_i}^{(j)}$.

Now assume we are given a large sample of projections $\{s_{t_1}^{(j)}, \dots, s_{t_{85}}^{(j)}\}_{j=1}^J$ for annual sea level rise anomalies compared to the 2015 value for the same time period. We model the relationship between the change in damage and change in sea level by a monotonic positive function $g(s|\beta)$ with parameters β , where $g(s|\beta) > 1$ for $s > 0$ and $g(s|\beta) < 1$ for $s < 0$. We may further incorporate uncertainty in the shape of the function g through the values of the parameters β . An empirical damage distribution for the future year t_i that accounts for uncertainty in damage, sea level rise and change in damage due to sea

level rise is then given by

$$\hat{F}_{d,t_i}(x) = \frac{1}{J} \sum_{j=1}^J \mathbb{1}\{g(s_{t_i}^{(j)}|\boldsymbol{\beta}^{(j)})d_{t_i}^{(j)} \leq x\}. \quad (2)$$

The distribution in (2) describes the projected damage distribution with no adaptation measures. In addition, we can incorporate an adaptation measure that protects against K cm of increased sea level from year t_k onwards. This results in a damage distribution given by

$$\hat{F}_{d,t_i}(x) = \begin{cases} \frac{1}{J} \sum_{j=1}^J \mathbb{1}\{g(s_{t_i}^{(j)}|\boldsymbol{\beta}^{(j)})d_{t_i}^{(j)} \leq x\}, & t_i < t_k \\ \frac{1}{J} \sum_{j=1}^J \mathbb{1}\{g(s_{t_i}^{(j)} - K|\boldsymbol{\beta}^{(j)})d_{t_i}^{(j)} \leq x\}, & t_i \geq t_k. \end{cases}$$

3.2. Limitations of the decision framework

4. Case studies

4.1. Data (PG)

Historical global mean temperature is obtained from *Hansen et al.* [2001]. Climate projections of global mean temperature are from the fifth climate model intercomparison project, CMIP5 [*Taylor et al.*, 2012]. The global mean sea level series is obtained from *Church and White* [2011]. We use local tide gauge data from the Permanent Service for Mean Sea Level, UK, which is the worldwide repository for national sea level data. Glacial isostatic adjustment for Bergen is obtained from *Simpson et al.* [2014].

Figure 1 shows uncorrected and corrected Bergen sea level data, and the relationship between the corrected Bergen data and the global sea level data. The time series regression uses an ARMA(1,1)-model [*Box and Jenkins*, 1970].

Figure 2 shows the simultaneous 90 % confidence region for Bergen sea level rise relative to 1999.

For the case study of sea level rise in Bergen, we use reported annual damage numbers from the Norwegian Natural Perils Pool which are available at <https://www.finansnorge.no/statistikk/skadeforsikring/Naturskadestatistikk-NASK/>.

4.2. Timing of adaptation measures (KdB, TT)

We estimate a damage distribution for Bergen in 2015 using annual data on storm surge damage from Hordaland and Rogaland counties over the period 1980-2015 obtained from the Norwegian Natural Perils Pool (NPP). The NPP data is aggregated to a county level and while only about 55% of the total population of Hordaland lives in Bergen, we do not correct for this as a substantial part of the remaining population lives away from the coast¹. In order to improve the parameter estimation, we include the data from Rogaland county which is the county directly south of Hordaland. Rogaland has a similar geography to Hordaland and a slightly smaller population with its main city, Stavanger, also located on the coast. The damage data prior to 2015 is adjusted to the 2015 level using the consumer price index for Norway. After the adjustment, we assume stationarity over the period and fit a single Burr distribution to the data, cf. (1). The histogram of the observed annual damages and the estimated distribution are given in Figure 3. The parameter estimates for the Burr distribution are $\hat{\alpha} = 1.27$, $\hat{\gamma} = 0.51$ and $\hat{\theta} = 0.002$.

For modelling the relationship between the change in damage and change in sea level we use the results of *Hallegatte et al.* [2013] for 15 European cities: Amsterdam, Athens, Barcelona, Dublin, Glasgow, Hamburg, Helsinki, Copenhagen, Lisbon, London, Marseille, Naples, Porto, Rotterdam and Stockholm. *Hallegatte et al.* [2013] estimate the mean annual flood damage in these cities in 2050 under no sea level change, 20 cm increase and 40 cm increase in sea level. We standardize their results for each city and consider

the relative change for 20 and 40 cm increase. We then perform a linear extrapolation to obtain estimated relative changes in damage for a large interval of changes in sea level rise, see Figure 4. Finally, the function g is obtained by sampling from this ensemble of functions with all 15 ensemble members considered equally probable.

4.3. Selection of adaptation measures(?) (MD)

A case study focusing on Denmark.

5. Conclusions

Acknowledgments. This work was funded by NordForsk through project number 74456 “Statistical Analysis of Climate Projections” (eSACP) and The Research Council of Norway through project number 243953 “Physical and Statistical Analysis of Climate Extremes in Large Datasets” (ClimateXL). The source code for the analysis is implemented in the statistical programming language R (<http://www.R-project.org>) and is available on GitHub at <http://github.com/eSACP/...>

Notes

1. TLT: Need to improve this discussion. Also, some of this discussion should probably be moved to the section on data.
